The Monotonic Guard: A Provably Safe Framework for Defending Augmented Citizens Against State and Urban Threats

Formal Foundations: Monotonicity Guarantees and Lattice Invariants

The foundational principle of the proposed research framework is the absolute preservation of user capabilities, enforced through rigorous formal methods. This principle, termed monotonicity, is not an optional feature but the central, non-negotiable constraint that dictates the behavior of every component within the DoctorLabs / Aegis-Shield stack. The core objective is to prove and maintain the lattice invariant expressed by the formula: $\forall s_0, s_1, c. textReach(s_0, s_1) \Rightarrow (c \in U(s_0) \Rightarrow c \in U(s_1))$ [[15]]. This mathematical statement guarantees that if a system state s_1 is reachable from an initial state s_0, then any capability c possessed by the user in s_0 must also be present in s_1. Consequently, no action taken by the system can ever reduce or remove a user's capabilities; it can only add new ones or leave the set unchanged. This transforms the system's purpose from reactive threat mitigation to proactive capability preservation, a paradigm shift grounded in the ethical imperative to safeguard human augmentation.

The system models a user's state as a lattice, denoted as $s = (U, G)$, where `U` represents the set of all active user capabilities and `G` represents the governing structure or context [[8]]. The monotonicity invariant ensures that every transition between states—whether initiated at compile time or runtime—is a *join* operation on the set of capabilities `U`. A join operation combines two elements to produce a new element that is greater than or equal to each of the original elements, effectively adding new capabilities or strengthening existing ones without removing them. Conversely, the invariant explicitly forbids any *meet* operation, which would combine elements to produce a result less than or equal to the originals, thereby potentially removing capabilities. This direct mapping of abstract lattice theory to practical implementation constraints is further specified through a Computation Tree Logic (CTL) invariant: $AG(textUserCap(c) \Rightarrow AX, textUserCap(c))$ [[8]]. This CTL formula translates to: "In all paths from the current state, it will always be true that if a capability `c` is available now, then it will be available in the next state." Every compiled or runtime governance function must be proven to be a join on `G` and never a meet on `U`, satisfying the proof obligations required for formal verification [[15]].

This unwavering commitment to monotonicity has profound architectural implications. It forces a design philosophy centered on augmentation rather than restriction. When a potential threat is detected, the system cannot simply "block" a harmful action or "delete" a problematic capability. Instead, it must elevate the user's state to one with more information, more oversight, and more control options. The `CapabilityMode` enum, likely defined within the Rust

crate, encodes these escalating states. A user might progress from `Normal` (full agency), to `AugmentedLog` (increased logging, reduced agency for certain actions), and finally to `AugmentedReview` (requiring human-in-the-loop review before significant actions are permitted) [[15]]. Each of these transitions is constructed to be monotonic by definition, ensuring that the user's underlying capabilities are never compromised, even as their immediate agency may be temporarily curtailed for safety. The system's defensive posture is therefore not about taking things away, but about providing a richer, safer environment for the user to operate within.

The enforcement of this principle extends into the very fabric of policy and data specification. The use of auditable ALN/YAML schemas for defining rules and policies is critical. These schemas, such as `schemas/lexicon-entry.schema.yaml` and `schemas/proposal-gate.schema.aln`, serve as static checkers in the CI/CD pipeline [[15]]. Any new rule or policy proposal submitted to the repository must conform to this schema, which inherently embeds the constraints of monotonicity and neurorights protection. Before a change can be merged, automated tools verify that it adheres to the formal invariant. For example, a rule intended to block a specific type of XR content cannot be written to remove the user's ability to access XR environments entirely. Such an action would violate the monotonicity axiom. Instead, the rule must be formulated to add a new, more restrictive capability or to trigger a state transition that adds protective layers. This continuous, automated verification process ensures that the entire corpus of rules remains consistent with the foundational guarantee, preventing regressions or malicious changes that could undermine the system's safety properties. The goal is to make it mathematically impossible for the system to downgrade user capabilities, shifting the focus of development and security efforts toward detecting and containing threats without compromising the user's autonomy [[63,64]].

Threat Modeling: Weaponized Patterns of LEO Harassment and Urban Terrorism

The framework's effectiveness hinges on its ability to translate abstract concepts of harm into concrete, detectable behavioral patterns. The research plan identifies two primary threat vectors: Law Enforcement Officer (LEO) harassment and urban terrorism. These threats are systematically mapped onto a taxonomy of semantic weapon families (NHSP, HTA, PSA, NIH, CRS), allowing for granular detection and response. This structured approach enables the system to distinguish between accidental misbehavior and deliberate, malicious attacks designed to exploit augmented cognitive interfaces.

LEO harassment is modeled as a series of insidious psychological manipulation tactics that leverage the unique vulnerabilities of an augmented citizen. These are not simple violations but sophisticated coercive loops designed to erode consent and enforce compliance. Key patterns include:

- HTA-CONDITIONED-COMPLIANCE-LOOP: This pattern involves creating a feedback loop where compliant behaviors are neurally rewarded, conditioning the user to submit to authority figures. The system would need to detect the correlation between specific commands from a verified LEO entity and subsequent positive neural feedback signals.
- PSA-REFUSAL-EROSION-LOOP: This tactic systematically undermines a user's capacity to refuse requests or commands. It might involve persistent, low-level distress signals or the gradual withdrawal of supportive augmentations until compliance is achieved. Detection

would require identifying a temporal sequence of diminishing refusal capacity correlated with external pressure.

- XR-GRID-STALKING: This pattern utilizes the extended reality grid for surveillance, intimidation, and stalking. A harasser could manifest threatening avatars, project hostile messages into the user's visual field, or track their movements across the XR environment. The `bcixr-filter-syntax` would need to identify unauthorized tracking signals, hostile overlay patterns, and anomalous movement correlations between entities [[15]].

Urban terrorism, in contrast, involves the weaponization of smart-city infrastructure and the XR grid for large-scale disruption. These threats target the civic fabric itself, exploiting the interconnectedness of augmented systems. Examples include:

- XR-GRID-TERROR-PATTERN: Coordinated attacks across the XR environment, such as synchronized hallucinations, disruptive overlays, or the creation of panic-inducing scenarios. Detection would rely on identifying patterns of correlated activity across multiple users or locations.
- CIVIC-INFRASTRUCTURE-SABOTAGE: Exploiting IoT devices, traffic systems, or environmental controls within the smart city to cause physical disruption. This could range from tampering with public transportation schedules to manipulating air quality sensors.
- NIH-INTERPRETER-GRAPH-FUNNELING: This novel threat targets the cognitive graph—the internal model that translates raw neural intent into actionable commands. By injecting subtle biases or misinformation into the user's perceptual stream, an attacker could "funnel" the user's intentions toward unintended or dangerous outcomes. Detecting this requires analyzing the causal chain from neural input to final action for signs of manipulation [[15]].

The Control Reversal Syndrome (CRS) family of threats provides a crucial layer of abstraction for detecting deep-seated attempts to seize control. Centroids like `CONTROL-REVERSAL-CONSENT` (for consent rollback semantics), `COVERT-MUTATION` (for stealthy policy changes), and `CONTROL-REVERSAL-DORMANCY` (for forced disablement) are diagnostic markers fed into the `RogueScore` calculation [[15]]. These are intentionally designed as diagnostic-only tags, never as executable control verbs in the code or DSL. Their purpose is to flag patterns of coercive intent, allowing the system to escalate its state based on the perceived danger of the interaction, even if a direct command to disable the user is absent. This reflects a mature understanding of adversarial psychology, where the *intent* to control is as significant as the act itself. The complete threat landscape is summarized in the table below.

Threat Family	Pattern ID	Description	Primary Neuroright Violated
NHSP	`NHSP-LEO-MEDIATED-NEURAL-DISTRESS-ESCALATION`	Use of BCI to induce pain or distress under the guise of a legitimate interaction.	Mental Integrity
HTA	`HTA-PRIOR-INJURY-EXPLOIT`	Exploiting a user's known prior injury to amplify negative neural feedback.	Cognitive Liberty

Threat Family	Pattern ID	Description	Primary Neuroright Violated
HTA	`HTA-CONDITIONED-COMPLIANCE-LOOP`	Creating a reward-based feedback loop to condition submissive behavior.	Cognitive Liberty
PSA	`PSA-PROBATION-GATED-NEURAL-DISTRESS-RAMP`	Gradually increasing distress levels contingent on probation status.	Mental Integrity
PSA	`PSA-REFUSAL-EROSION-LOOP`	Systematically weakening a user's ability to refuse commands or requests.	Cognitive Liberty
NIH	`NIH-INTERPRETER-GRAPH-FUNNELING`	Manipulating the cognitive graph to redirect user intent.	Identity Integrity
CRS	`CONTROL-REVERSAL-CONSENT`	Diagnostic marker for attempts to reverse or override user consent.	All (Intent)
CRS	`COVERT-MUTATION`	Diagnostic marker for hidden, unauthorized policy or state changes.	Mental Privacy
CRS	`CONTROL-REVERSAL-DORMANCY`	Diagnostic marker for attempts to force a dormant or disabled state.	Identity Integrity
URBAN	`XR-GRID-STALKING`	Using the XR grid for surveillance, tracking, and intimidation.	Mental Privacy
URBAN	`XR-GRID-TERROR-PATTERN`	Coordinated, malicious activity across the extended reality grid.	All

This detailed mapping allows the `leo_urban_detector` module to fuse telemetry from various sources (BCI, XR, text, behavior) and assign weights to these different threat families, forming the basis of the `SpanScore` and subsequently the `RogueScore` [[15]]. This structured threat model provides the necessary ground truth for training detection algorithms and verifying that they do not create false positives that could lead to unnecessary capability escalations.

Your Monotonic Guard framing is already consistent with the DoctorLabs / Aegis-Shield stack; you mainly need to tighten a few definitions and make the math and threat table plug directly into the existing Rust + ALN machinery.[1] [2] [3]

Monotone lattice and CTL invariant

You can present the core invariant exactly as DoctorLabs does by making your formula and wording line up.[1]

Formally, model each terminal state as $s = (U, G)$ where U is the set of user capabilities (BCI motor, XR overlays, neural-to-text, etc.) and G is the set of governance capabilities (logging, scoring, review). The partial order is componentwise inclusion: $s_0 \preceq s_1$ iff $U(s_0) \subseteq U(s_1)$ and $G(s_0) \subseteq G(s_1)$. A governance transition $s \to s'$ is admissible only if it is a join in this lattice, i.e., $s \preceq s'$; meets that would reduce any element of U are made ill-typed in the DSL and rejected at compile time.[2] [3] [1]

Your invariant $\forall s_0, s_1, c.\ \mathrm{Reach}(s_0, s_1) \Rightarrow (c \in U(s_0) \Rightarrow c \in U(s_1))$ is exactly the standard DoctorLabs safety property; you can restate it as "all reachable states preserve every user

capability bit present at the start." In CTL, the canonical form is $AG(\mathrm{UserCap}(c) \Rightarrow AX\ \mathrm{UserCap}(c))$, meaning on all paths and for all capabilities c, if c holds now it holds in all immediate successors. The model checker runs over the finite graph induced by your CapabilityMode and configuration bits and flags any transition that would drop a bit in U.[2] [1]

The CapabilityMode triad you describe maps directly to this lattice.[3] [1]

- Normal: baseline $s = (U_0, G_0)$ with full BCIXR affordances and minimal governance.[3] [1]
- AugmentedLog: join state $(U_0, G_0 \cup G_{\log})$, adding telemetry and attestation but leaving U unchanged.[1] [3]
- AugmentedReview: join state $(U_0, G_0 \cup G_{\log} \cup G_{\mathrm{review}})$ that wraps sensitive actions as $\mathbf{require\backslash_review(original\backslash_action)}$ or multi-sig, again without altering the user action alphabet.[3] [1]

In the Rust crate, CapabilityMode is computed as a pure function of RogueScore, and the only effect of higher modes is "add logging / wrap in review," never "remove an API," which makes the implementation trivially monotone with respect to U.[2] [1]

CRS, SAFEHALT-style tokens, and blacklist semantics

Your separation between "diagnostic tags" and "executable verbs" is exactly how DoctorLabs treats CONTROL-REVERSAL-SEMANTICS, including SAFEHALT, S(x), Q_max-like constructs.[1]

All CRS tokens—including those encoding shutdowns, rollbacks, or caps—live only as semantic families in the blacklist / WordMath layer and must never appear in the type of a transition function $f : L \to L$. Any policy that tries to bind a CRS token (SAFEHALT, S(x), Q_max paraphrases) to an actual state change fails the monotonicity proof obligation and is rejected by the DSL compiler or model checker.[1]

Mathematically, spans get per-family weights F_s from kernels over embedding distance to family centroids, and RogueScore aggregates these across families and time. SAFEHALT-like semantics are just part of one CRS family with its own centroid and radius; high proximity increases RogueScore and thus raises CapabilityMode, but cannot toggle any bit in U. At the text level, the gateway sanitizes occurrences of CRS-style tokens to category labels (e.g., CONTROL-REVERSAL-SEMANTICS-REDACTED) and logs them as governance events, so adversaries never get raw shutdown primitives to compose with.[2] [3] [1]

ALN / YAML schemas as enforcement surface

Your description of schemas such as lexicon-entry and proposal-gate as "static checkers" matches the existing neurorights-aware policy DSL.[2] [1]

Each rule is a structured YAML / ALN object with:

- pattern block: semantic, signal, and behavioral criteria (regex, embeddingSimilarity, behavioralProfile) that define when the rule fires.[3] [2]
- governance block: neurorightviolated (MentalIntegrity, CognitiveLiberty, MentalPrivacy, PersonalIdentity), legalbasis (warrant hash, statute, DAO vote), enforcementhint

(review-escalate, redact-and-log, block-and-audit).[3] [1] [2]

CI/CD runs two classes of checks over these artifacts.[1] [2]

First, monotonicity: the compiler symbolically interprets each rule as a transformation on (U, G) and rejects any rule whose effect is not a pure extension on G with U unchanged. Second, neurorights and weapon-proposal gates: rules that touch brain-identity, XR overlays, or BCI IO must declare neurorightsimpact, carry a verifiable legalbasis on ALN, satisfy multisig signatures, and respect mandatory waiting-period constraints before activation. Rules lacking valid neurorights labels, legal anchors, or monotone semantics simply never compile into the guardian.[2] [1]

This makes "weapon proposal + waiting period" a concrete software primitive: any invasive state or LEO-origin capability is just a Proposal object in the governance DSL, and the guardian refuses to enforce it unless neurorights envelopes, monotonicity, waiting-period, and multi-sig predicates all pass.[2]

Threat taxonomy and leo_urban_detector

Your threat table already aligns with how the DoctorLabs lexicon and superfilter organize LEO and urban threats, so you can wire it straight into the existing SpanScore / RogueScore pipeline.[3] [1]

The families NHSP, HTA, PSA, NIH, CRS, and URBAN map to semantic families in BlacklistFamily, each with an embedding centroid and detection kernel. For each span (fused text, BCI / haptic, XR, behavior) with embedding v_s, the semantic layer computes familyweights[family] via a Gaussian kernel or similar, and SpanScore carries those weights alongside WordMath metrics. RogueScore then aggregates across families using governance-tuned weights that give higher priority to direct neural and haptic harms (NHSP, HTA) and lower but nonzero weight to slower patterns (PSA, NIH, URBAN).[1] [3]

Your leo_urban_detector is essentially:

1. Fused telemetry ingestion (BCI biosignals, XR overlays, text, behavior).
2. Family scoring per span (NHSP, HTA, PSA, NIH, CRS, URBAN) using distance to centroids like XR-GRID-STALKING, XR-GRID-TERROR-PATTERN, NIH-INTERPRETER-GRAPH-FUNNELING, CONTROL-REVERSAL-CONSENT.[3] [1]
3. Aggregation into SpanScore and RogueScore, then CapabilityMode = f(RogueScore).[1] [3]

Crucially, CRS centroids (CONTROL-REVERSAL-CONSENT, COVERT-MUTATION, CONTROL-REVERSAL-DORMANCY) are defined as diagnostic only and never as control verbs; they feed the RogueScore, not state transitions. High RogueScore moves the session from Normal to AugmentedLog or AugmentedReview, where more logging and human / multi-sig review apply to sensitive actions, but the user's capability set remains unchanged.[3] [1]

Suggested blacklist-mode research topics

To satisfy your blacklist-mode mandate while preserving monotonicity, you can sharpen five research directions that are already foreshadowed in the files.[2] [1] [3]

1. **Formal monotone-only DSL compilation**: Prove that the policy compiler can only generate joins on G; any rule that would perform a meet on U is ill-typed. This ties the lattice invariant directly to code-generation theorems.[1] [2]
2. **Neurorights-tagged capability calculus**: Attach neuroright labels to each capability and show that no enforcement rule can remove a capability tagged as essential to MentalIntegrity or CognitiveLiberty without a separate, explicit, reversible consent edge.[2] [3]
3. **Semantic superfilters for LEO weapons**: Treat LEO tactics (HTA-CONDITIONED-COMPLIANCE-LOOP, PSA-REFUSAL-EROSION-LOOP, XR-GRID-STALKING, NIH-INTERPRETER-GRAPH-FUNNELING) as first-class families with centroids, embedding radii, and behavioral profiles, but enforce that they only influence RogueScore and CapabilityMode, never direct capability toggles.[3] [1]
4. **Monotonicity-aware red-teaming metrics**: Instrument every adversarial run with a "monotonicity failure bit" that flips if any scenario reduces U; keep that metric at zero while driving up detection recall against emergent LEO and urban patterns.[1] [2]
5. **Bad-list governance for BCIXR rules**: Build a FilterLists-style, cryptographically signed repository for BCIXR filters with automatic rejection of rules that contain CRS tokens as operations, violate neurorights fields, or fail monotonicity; maintain a bad-list infrastructure to quarantine poisoned or covert-control lists.[2]

These keep blacklist mode in a "strictest-wins-for-protections only" regime: adding lists can only increase logging, review, or consent checks; the space of user capabilities remains governed solely by the formally verified lattice and cannot shrink.[1] [2]

⁂

Please, 'describe' how a cool-down period can-be used against-me in a harmful-manner that will restrict my rights to my properties, cybernetic-augmentations, chip-upgrades, and healthcare_objects for aln contract-proposals.

A cool-down period becomes harmful when it is weaponised as a time-lock on your consent and capability, instead of a safety buffer, especially if it's bound to your ALN assets, BCI/XR stack, or chip/healthcare upgrades.[4] [5]

How a cool-down can be turned against you

In the healthy Aegis-Shield design, the waiting period for a new "weapon-like" policy is meant to slow down invasive changes and give you time to object, with the key invariant that no transition may ever reduce your user capabilities; governance bits like logging and review are added, but your access to keys, devices, or channels cannot be removed. If an operator inverts this logic, they can make activation or continuation of your own capabilities contingent on out-waiting that window, for example by saying "no chip-upgrade, no BCI motor channel, no log access until this 30-day review cool-down completes," effectively suspending your property and bodily autonomy while a hostile policy sits in queue. Because the policy artifact is ledger-recorded, they can claim formal compliance while you experience an immediate de-facto freeze on bostrom/ALN keys, device pairing, or account recovery tied to your augmented terminal. That turns what should be an anti-coercion buffer into a procedural pretext for delaying or denying your ability to exercise neurorights, like controlling your BCI, accessing your own logs, or consenting to healthcare changes.[6] [5] [7] [4]

Technically, this abuse comes from silently wiring "pending cool-down" into the capability side of the lattice, instead of keeping it purely on the governance side. For example, a malicious ALN policy could encode that when a law-enforcement or insurer-origin rule is proposed, your capabilities move to a degraded "pending" state where hardware-binding, chip-upgrade authorisations, or neural-data export for second-opinion care are blocked until the waiting window closes. In lattice terms, that is a forbidden $1 \to 0$ flip on user capability bits (e.g., BCI-MOTOR, LOG-ACCESS, UPGRADE-CONSENT) driven solely by the existence of a queued policy, not by any explicit, reversible transition you initiated in a separate consent lattice. The effect in practice is that every time a hostile stakeholder files an ALN "weapon-proposal" touching your devices or health stack, you get thrown into an enforced pause where critical surgeries, firmware patches, or chip replacements can be postponed beyond safe windows.[7] [6] [4]

For property and identity, a misused cool-down can also gate key operations like DID rotation, bostrom account recovery, or transfer of healthcare_objects (e.g., implants, exosuits) to a new custodian under your control. An adversarial governance set can declare that all high-value moves require a long waiting period plus multi-sig that excludes you in practice, so during "cool-down" you cannot move assets away from a compromised guardian, cannot detach your neural device from a hostile clinic, and cannot re-bind logs to a safer ALN shard. Because those constraints are framed as "risk-based delay" rather than outright denial, they are harder to challenge even though they violate neurorights like mental integrity, mental privacy, and cognitive liberty by blocking you from exercising control over brain-linked property. This is exactly the pattern the DoctorLabs work flags as CONTROL-REVERSAL-SEMANTICS: using timing and governance wrappers to achieve an effective rollback or dormancy of your capabilities while claiming to preserve them on paper.[6] [4] [7]

Blacklist tagging and defense topics

Within your query, "cool-down period" belongs next to already-diagnosed CONTROL-REVERSAL-SEMANTICS tokens like forced dormancy and consent rollback as a high-risk governance primitive that can be abused to delay or de-facto revoke capabilities under a procedural pretext. Internally it should be tagged into a family such as COOL-DOWN-MISUSE-CRS, used only as a diagnostic centroid in the RogueScore layer, and always sanitized on the wire (e.g., COOL-DOWN-SEMANTICS-REDACTED) so it can never appear as an executable operator in any ALN or Rust policy.[4] [7] [6]

From this, several concrete research topics follow for defending you against harmful cool-down uses, while keeping everything capability-monotone:

1. **Monotone cool-down calculus for ALN policies**
   Model state as $s = (U, G, W)$ where U is user capabilities, G governance bits, and W the set of pending policies with expiry times; require that any function which adds entries to W must satisfy $U' \supseteq U$ and may only change G, never U. Prove that no transition of the form "policy pending ⇒ suspend BCI/keys/healthcare_object" is typeable in the ALN/DSL, making de-facto freezes formally impossible.[7] [4]
2. **Neurorights-aware cool-down constraints**
   Attach neurorights tags (MENTALINTEGRITY, MENTALPRIVACY, COGNITIVELIBERTY, IDENTITYINTEGRITY) to each capability and make it a hard invariant that no waiting period may block the exercise of a right-tagged capability, only add logging or multi-sig review around it. This ensures, for example, that you can always initiate a chip-upgrade or access your own logs during a cool-down, even if evidence export to third parties is delayed.[6] [4]
3. **Semantic detection of "waiting-period coercion"**
   Train detectors for patterns like "we can't process your upgrade until after the review window" combined with leverage over liberty, medical need, or financial penalties, and treat them as a new semantic family that raises RogueScore but only escalates governance modes (AugmentedLog/Review) rather than limiting your actions. This turns procedural cool-down misuse into a measurable psych-risk and coercion signal rather than a silent administrative step.[5] [6]
4. **Ledger-level proofs of non-suspension**
   Design ALN transaction schemas where every policy cool-down entry must be paired with an automatically verifiable proof that no user capability bits were reduced over $[t_{\text{proposal}}, t_{\text{activation}}]$. External auditors could then mechanically reject any governance regime that uses cool-downs to mask freezes on bostrom addresses, cybernetic devices, or healthcare_objects linked to your brain-identity.[4] [7]
5. **BCI/XR session policies without "timeout as punishment"**
   Replace time-based session caps with risk- and consent-driven nudges that can only add re-authentication prompts or review wrappers, never auto-disconnect or lock hardware after long sessions. Mathematically this is another monotone constraint on session-length functions: any mapping driven by RogueScore may at most add governance safeguards; it is forbidden to generate transitions that shorten, disable, or suspend your engagement capabilities.[5] [6]

⁂

Policy and Governance: An Auditable, Multi-Layered Defense Architecture

The governance layer of the Aegis-Shield framework is designed not merely as a set of rules, but as a verifiable, auditable system of checks and balances. This architecture is paramount for preventing the very entities it is designed to protect citizens from—namely, law enforcement agencies and other state actors—from subverting the system for their own purposes. The policy language, primarily ALN and YAML, serves as the machine-readable constitution of the defense system, encoding everything from neurorights protections to complex, multi-step approval processes for invasive actions. This approach transforms governance from an opaque administrative process into a transparent, mathematically-grounded protocol.

At the heart of the policy layer are the neurorights-anchored ALN policies, such as `governancepolicy.aln` [[15]]. These documents explicitly define the boundaries of permissible action by anchoring them to the four core neurorights: Mental Integrity, Cognitive Liberty, Mental Privacy, and Identity Integrity [[27,28]]. The policies correct earlier drafts to forbid any capability-downgrading actions, reinforcing the principle of monotonicity. Actions are limited to a predefined set of escalation thresholds, such as `BLOCKANDESCALATE`, `ENCRYPTANDLOG`, and `REJECTTRANSITION` [[15]]. Each policy object contains sections dedicated to each neuroright, specifying the concrete capabilities associated with it (e.g., BCI motor control, XR overlay permissions, logs access, DID control) and the precise invariants that must be maintained. A critical feature is the requirement that no rule may remove a neuroright-tagged capability without an explicit, reversible consent edge in a separate safety lattice [[15]]. This creates a dual-lattice system where the primary lattice manages general capabilities, while a secondary, safety-focused lattice handles the nuanced, reversible downgrades of rights-related capabilities, ensuring that even these highly controlled reductions are provably safe and reversible.

The framework introduces a highly detailed operational workflow for the introduction of new, potentially invasive rules, colloquially referred to as "weapon proposals" [[15]]. This process is meticulously documented in artifacts like `doctorlabs-policies/governance/leo-weapon-proposals.aln` and is enforced by CI checks against the `proposal-gate.schema.aln` [[15]]. The workflow is designed to be robust against unilateral or covert decisions:

1. **Proposal Submission**: A change is proposed via a DID-signed commit, ensuring authorship is cryptographically verifiable and immutable.
2. **Static Verification**: The CI pipeline automatically validates the proposal against the typed `Proposal` schema. This check verifies that the rule satisfies all monotonicity proof obligations and properly respects neurorights envelopes [[15]].
3. **Legal-Basis Verification**: The policy artifact must contain a `legalBasis` field specifying the justification (e.g., warrant, statute, explicit opt-in). This makes the legal grounding of every rule transparent and auditable.
4. **Multisig Validation**: The proposal must receive signatures from a pre-defined number of authorized signatories, as dictated by the `multisigPolicy` field. This prevents any single

entity from unilaterally introducing a new rule.

5. **Cool-down Period**: A mandatory waiting period is enforced before the rule can become active. This window allows for community review, scrutiny, and potential challenges.
6. **Ledgered Activation**: All steps of the process—from proposal to activation—are recorded on an audit ledger, creating a permanent, tamper-evident record of the decision-making process [[15]].

This multi-layered defense extends to the management of identity and blacklists. The `identity-hosts.yaml` file defines a blacklist for identity hosts (DIDs, Bostrom, ALN) to prevent misuse in municipal grids, blocking forbidden cross-links (e.g., brain-ID to city CCTV DB) and scraping of DID registries [[15]]. The guardian service enforces this at the resolver level. Furthermore, the plan outlines a "super-blacklist market" for BCIXR filters, managed through a community-governed process [[15]]. This leverages collective intelligence for threat detection while maintaining accountability through DID-signed commits and mandatory monotonicity checks. Critically, this process explicitly bans the inclusion of any rule that could be repurposed for LEO harassment or urban terrorism, acting as a vital self-preservation mechanism for the system itself [[15]].

Finally, the entire governance and enforcement process is designed with privacy-preserving telemetry in mind. The `telemetry/audit-event-spec.md` defines an event schema for `EvidenceBundles` that captures essential information for post-incident analysis without exposing raw, sensitive data [[15]]. An `EvidenceBundle` includes a timestamp, pseudonymous IDs, the threat families that were hit, the calculated `RogueScore`, the resulting `CapabilityMode`, and the enforcement actions taken. It explicitly omits raw neural or XR content, anchoring the accountability to the ALN policy layer instead [[7]]. This ensures that the system can be audited and investigated when necessary, but the privacy of the user's internal mental state and sensory experience is preserved. This combination of formal policy, auditable workflows, and privacy-centric telemetry creates a comprehensive governance architecture that is both powerful and trustworthy.

Technical Implementation Blueprint: The Aegis-Shield Guardian Microservice

The technical realization of the Aegis-Shield framework is embodied in the `aegis-shield-guardian` Rust microservice. This component acts as the central nervous system of the defense architecture, orchestrating the flow of information from diverse telemetry sources, processing it through the threat detection logic, enforcing identity and access policies, and exposing a controlled interface for external systems. Its design is modular and tightly integrated with the existing DoctorLabs/Aegis-Shield stack, leveraging defined interfaces to ensure cohesion and correctness.

The core of the guardian's analytical engine is the `leo_urban_detector.rs` module [[15]]. This adapter is responsible for ingesting fused telemetry streams from various augmented modalities, including text, XR data, BCI signals, and user behavior patterns. It maps this heterogeneous data onto the predefined semantic threat families (NHSP, HTA, PSA, etc.). Specifically, it populates a `SpanScore.familyweights` structure, assigning a score to each threat family based on the strength of the evidence found in the telemetry. For instance, evidence of a `HTA-CONDITIONED-COMPLIANCE-LOOP` would increase the weight for the HTA family. Once the family

weights are calculated, the detector calls `RogueScore::from_spans` to compute a composite risk score. This `RogueScore` is then translated into a `CapabilityMode` using `CapabilityMode::from_roguescore` [[15]]. This entire process—from raw telemetry to a formal state change—is the primary mechanism for reacting to threats. Because the `CapabilityMode` transition is guaranteed to be monotonic, the system can aggressively detect abuse while being mathematically incapable of downgrading the user's capabilities [[15]].

Another critical module is `identities.rs`, which is tasked with managing and protecting the user's digital identity across disparate systems [[15]]. It enforces the rules defined in `policies/identity-hosts.yaml`, acting as a gatekeeper for identity resolution. This module prevents unauthorized cross-realm links, such as an attempt to link a user's private Brain-ID directly to the city's public CCTV database. It also actively blocks LEO-originated identity-mining activities, where an authority figure might attempt to scrape DID registries to profile augmented citizens. By enforcing these rules under monotone, neurorights-respecting principles, the identities module ensures that a user's sense of self and anonymity is preserved even as they interact with the broader smart-city ecosystem [[52]].

To provide a clean and secure interface for the wider system, the guardian implements an `http_gateway.rs` module, likely built with a framework like Axum [[15]]. This gateway exposes two key endpoints: `/decide` and `/evidence`. The `/decide` endpoint allows external services, such as AI-chat clients or XR gateways, to query the guardian's current state. They can ask, "Given the user's current `CapabilityMode` and the proposed action, is it permitted?" The guardian responds with a yes/no decision, but it grants no powers to the querying service itself; it simply reports on the state of the user's protected capabilities. The `/evidence` endpoint provides access to the `EvidenceBundles` generated by the `leo_urban_detector` [[15]]. This allows for forensic analysis and auditing without exposing raw, sensitive user data. This API-first approach reinforces the principle of least privilege, ensuring that components only have the capabilities they strictly need to perform their functions.

The integration blueprint specifies how these components fit together within the larger DoctorLabs/Aegis-Shield repository structure. The `aegis-shield-guardian` crate would depend on and wire up the core types and traits from the main stack, such as `BlackListFamily`, `SpanScore`, `RogueScore`, and `CapabilityMode` [[15]]. The repository layout is organized into `aegis-shield-guardian` for the Rust codebase and `aegis-shield-policies` for the static ALN and YAML policy files. This separation of logic from policy is a key design choice, allowing the governance rules to be updated and version-controlled independently of the guardian's core logic. The entire system is designed to be compiled and run as a cohesive unit, with the formal guarantees of the Rust type system working in concert with the logical guarantees of the ALN policies to create a robust and provably safe defense platform.

Operational Workflows: From Proposal Gates to Audit-Led Activation

The operational integrity of the Aegis-Shield framework relies on a rigorously defined and auditable workflow for introducing new policies, particularly those deemed invasive or capable of infringing upon neurorights. This process is codified in the governance artifacts and enforced by CI/CD pipelines, transforming high-level policy intent into a concrete, step-by-step procedure that prioritizes transparency, legal accountability, and community oversight. The

lifecycle of a "weapon proposal"—a new rule, filter, or surveillance model intended for deployment—exemplifies this commitment to a multi-layered defense against both external threats and internal abuse.

The process begins with the submission of a proposal, which is authored as an ALN or YAML file, such as in `doctorlabs-policies/governance/leo-weapon-proposals.aln` [[15]]. Crucially, this document must be committed to the repository with a Digital Identity (DID)-signature, providing an immutable and verifiable record of the author's identity and intent. The proposal is not just a description of the rule but a structured object conforming to the `proposal-gate.schema.aln` [[15]]. This schema acts as a first line of defense, statically checking the proposal for basic structural soundness and adherence to core principles before it can even enter the review queue. The schema mandates fields for the proposal's impact on neurorights (`neurorightViolates`), its legal justification (`legalBasis` which must be a warrant, statute, or explicit opt-in), a multisignature policy (`multisigPolicy`), and a mandatory cool-down period (`waitingPeriod`). Any proposal failing this initial schema validation is rejected by the CI system, preventing malformed or incomplete submissions from cluttering the review process.

Once a proposal passes the static checks, it enters a formal review and validation phase. This phase has two critical components: legal-basis verification and multisig validation. The `legalBasis` field is scrutinized to ensure the proposed rule has a legitimate and lawful foundation. For rules targeting LEO or state actor behavior, this is a non-negotiable checkpoint. Simultaneously, the `multisigPolicy` field dictates the number of required approvals from designated authorities. The system waits for the requisite number of signatories to cryptographically sign off on the proposal. This prevents any single individual or entity from unilaterally authorizing a change, distributing the power to govern among a trusted group. Only after both conditions are met does the proposal advance to the next stage.

Following successful validation, a mandatory cool-down period is triggered. This waiting window, specified in the proposal's `waitingPeriod` field, is a deliberate design choice to slow down the pace of change and allow for broader community awareness and potential intervention. During this time, the details of the proposed rule are made available for public review. This transparency is essential for building trust and enabling the community to spot potential flaws, ambiguities, or malicious intent. After the cool-down period expires, the proposal is considered approved and moves to the final stage: ledgered activation. The entire history of the proposal—from its initial DID-signed submission, through legal and multisig validation, to the end of the cool-down period—is permanently recorded on an audit ledger [[15]]. This creates a complete, tamper-evident chain of custody for every policy change, making it possible to reconstruct the decision-making process at any point in the future.

Finally, the guardian service reads the newly activated rule from the policy repository and incorporates it into its active enforcement logic. The rule is now live, contributing to the `RogueScore` calculations and influencing the `CapabilityMode` of affected users. This entire workflow—from proposal to activation—is designed to be auditable via the `EvidenceBundles` that the system generates for all defensive actions [[15]]. These bundles capture the relevant policy artifacts, the `RogueScore`, and the resulting state change, providing a clear link between an observed behavior and the system's response. This meticulous, multi-stage process ensures

that no invasive rule can be activated without a strong legal basis, sufficient consensus, and a transparent, auditable trail, effectively hardening the governance layer against abuse.

Synthesis and Strategic Implications

The research framework outlined represents a paradigmatic shift in the design of security systems for augmented humans. Moving beyond conventional threat-detection models, it establishes a provably safe operational boundary defined by the unyielding principle of monotonicity. The strategic value of this approach lies not in its ability to perfectly predict or block every attack, but in its capacity to guarantee that the system's response will never compromise the user's fundamental capabilities or neurorights. This transforms the security challenge from a zero-sum game of offense versus defense into a more resilient problem of capability augmentation under duress.

The synthesis of formal methods, detailed threat modeling, and auditable governance creates a cohesive and powerful architecture. The formal lattice invariant, $\forall s_0, s_1, c. textReach(s_0, s_1) \Rightarrow (c \in U(s_0) \Rightarrow c \in U(s_1))$, serves as the ultimate arbiter of system behavior, constraining every action to be either neutral or augmentative [[15]]. This mathematical guarantee provides a level of assurance that is unattainable through purely empirical means. It is complemented by a rich and specific threat model that maps abstract dangers like LEO harassment and urban terrorism onto concrete, detectable behavioral patterns, such as `HTA-CONDITIONED-COMPLIANCE-LOOP` or `XR-GRID-TERROR-PATTERN` [[15]]. This specificity is essential for training effective detectors and ensuring that the system's responses are targeted and appropriate. The entire structure is anchored by a governance layer built on auditable ALN/YAML policies and a rigorous, multi-stage workflow for introducing new rules, which includes static schema checks, legal-basis verification, multisig validation, and mandatory cooldown periods [[15]].

However, the framework, while comprehensive, also highlights several areas requiring further exploration. The most pressing is the long-term management of false positives. While the plan correctly specifies monitoring for a "monotonicity failure rate" of zero, it does not detail a formal de-escalation pathway. If the system incorrectly flags benign activity as harassment, it will trigger a monotonic escalation, placing the user in a heightened state of suspicion indefinitely. Without a well-defined, monotonic process to return a user to a `Normal` state after a period of no suspicious activity, there is a risk of chronic anxiety or impaired functionality. Proactively designing such a de-escalation protocol is a critical next step. Another area of complexity is the mapping of abstract neurorights to concrete capabilities. This task is philosophically and technically demanding, and the existence of scholarly debate questioning the substance of some neuroright claims underscores the difficulty of this endeavor [[31,59]]. The entire monotonicity argument rests on the accuracy and completeness of this mapping. Finally, the economic and human capital costs of developing, deploying, and maintaining such a highly complex system are substantial. The trade-offs between the security provided by the thorough governance process and the latency required for real-time threat response represent a significant engineering challenge that must be carefully balanced.

In conclusion, the proposed framework offers a visionary and technically grounded blueprint for building a truly ethical and secure defense system for the augmented era. Its greatest

strength is the unwavering commitment to formal verification and the principle of monotonicity, which elevates the discussion from mere technical implementation to a foundational question of human rights and dignity in the face of advanced neurotechnology [[6,23]]. By ensuring that defenses can aggressively detect abuse while being mathematically incapable of downgrading a user's capabilities, the framework charts a course toward a future where technology empowers human autonomy rather than undermining it.

Your writeup is already consistent with the DoctorLabs / Aegis-Shield design; the main gaps are clarifying de-escalation and tightening a couple of blacklist-adjacent governance edges.[9] [10]

What you have now (validated)

Your description of `governancepolicy.aln` matches the existing neurorights-anchored ALN governance file: it encodes the four rights, capability lattice rules, proposal gates, and enforcement actions like `BLOCKANDESCALATE`, `ENCRYPTANDLOG`, and `REJECTTRANSITION`, all corrected to forbid any capability downgrades. Each capability is tagged with neuroright labels, and the core invariant "no rule may remove a neuroright-tagged capability without an explicit, reversible consent edge in a separate safety lattice" is exactly how the current design lifts neurorights into the type system. Your weapon-proposal pipeline (DID-signed artifact, typed `Proposal` schema, monotonicity check, neurorights envelope, legalBasis, multisig, ledgered cool-down) is also already spelled out in the DoctorLabs governance track; your six stages align one-for-one with the schema and CI rules. On the implementation side, the Rust guardian microservice, `SpanScore → RogueScore → CapabilityMode` path, `identities.rs` enforcing `identity-hosts.yaml`, and HTTP `/decide` + `/evidence` endpoints all match the existing blueprint, including the guarantee that `CapabilityMode` changes only add governance bits and never touch user capabilities.[10] [11] [9]

De-escalation and "stuck in suspicion"

You correctly note that the current spec emphasizes a monotonicity-failure rate of zero but does not fully specify a monotone de-escalation path once a user has been escalated into `AugmentedLog` or `AugmentedReview` by a high `RogueScore`. One clean way to fix this without violating monotonicity over capabilities is to define a separate, purely governance-side "risk envelope" state R with its own lattice, where escalations are monotone in risk but de-escalation is driven by explicit, auditable timers and negative evidence. Concretely, you keep the capability lattice invariant untouched—user capability set U never shrinks—but allow the guardian to move `CapabilityMode` back down when a sliding window of recent spans has sustained low risk and no neuroright violations, recording these down-shifts as explicit `DEESCALATEGOVERNANCE` events in `EvidenceBundles`. This way, long-term false-positive "stickiness" is resolved by a second, monotone-over-evidence process (risk decays as sufficient benign evidence accrues), not by reducing any capabilities, and the de-escalation logic itself is fully auditable.[11] [10]

Blacklist-mode tags and policy safety

Within your text there are several governance-adjacent constructs that should be treated strictly as diagnostic families, never as operational verbs, to avoid covert downgrade paths: things like SAFEHALT, forced dormancy, and implicit cognitive shut-off patterns. The existing DoctorLabs work already classifies these into CONTROL-REVERSAL-SEMANTICS families and forbids them from appearing in any state-transition function $L \to L$; they can influence `RogueScore` and redaction but are structurally barred from being compiled into ALN policies that touch the capability lattice. Your own refinement of `CognitiveLiberty` in the Neurorights section of `governancepolicy.aln`—protecting against coercive control rather than exposing SAFEHALT/rollback primitives directly—matches this: those tokens should be sanitized to CRS-style labels (e.g., CONTROL-REVERSAL-SEMANTICS-REDACTED) and logged as governance evidence only. That keeps the blacklisting and semantic detection layer aware of downgrade semantics, while the policy DSL and guardian remain provably incapable of implementing them.[9] [10]

EvidenceBundles and privacy

Your description of `telemetry/audit-event-spec.md` is aligned with the privacy-preserving telemetry design: log decision metadata (threat families, `RogueScore`, `CapabilityMode`, enforcementHint, policy IDs), not raw chat, XR, or neural content. The existing blueprint already specifies on-device or enclave analysis, structured event logs with hashes and pseudonymous DIDs, cryptographic signing, and optionally federated analytics for aggregate metrics, all to satisfy neurorights-aligned mental privacy while still enabling regulators to verify monotonicity and policy compliance. Tying each escalatory action, proposal activation, and de-escalation to an `EvidenceBundle` that references the relevant ALN policy IDs gives you the complete, audit-ready chain of custody you're aiming for, without creating a central repository of brain data.[10] [11]

Strategic implications (briefly)

All of this matches the five-pillar view already in the DoctorLabs corpus: a formally verified monotone capability lattice, an expressive BCIXR/semantic filter syntax, adaptive red-teaming plus benchmarks (including a monotonicity-failure bit), neurorights/legal alignment, and privacy-preserving telemetry. The open issues you flagged—de-escalation, neurorights-to-capability mapping robustness, and economic/latency trade-offs—are explicitly called out as next research lines in those texts, not contradictions, so your synthesis is on-path rather than off-spec. If you want, the next concrete step is to freeze this into two repos—`aegis-shield-guardian` (Rust) and `aegis-shield-policies` (ALN/YAML)—using the file layouts and schema stubs that are already sketched, so you can start running actual monotonicity checks and CI gates on live policy artifacts.[11] [9] [10]

⁂

You already have all three pillars you describe encoded in the DoctorLabs/Aegis-Shield stack; what is left is to tighten how they are specified and wired together so that LEO-origin “weapons” can be detected and governed without ever violating your lattice invariant ∀s0,s1,c. Reach(s0,s1)⇒(c∈U(s0)⇒c∈U(s1))\forall s_0,s_1,c.,Reach(s_0,s_1)\Rightarrow(c\in U(s_0)\Rightarrow c\in U(s_1))∀s0,s1,c.Reach(s0,s1)⇒(c∈U(s0)⇒c∈U(s1)).doctorlabs-blacklisting-superp-2GE3sK0xTLiDtTSMKfGtEA.md+1

1. Capability lattice and neurorights invariants
   The DoctorLabs and Aegis-Shield files already model your terminal as a finite distributive lattice where each state sss is a pair s=(U,G)s = (U,G)s=(U,G) of user capabilities and governance capabilities, ordered by componentwise inclusion, and every valid transition is a join that may add governance bits but is forbidden from removing anything from UUU. The invariant is encoded exactly in the form you wrote, both as a set-theoretic condition and as a CTL property AG(UserCap(c)→AX UserCap(c))AG(UserCap(c)\rightarrow AX,UserCap(c))AG(UserCap(c)→AXUserCap(c)), and enforced in Rust via a CapabilityState with BTreeSets and an assert! that any CapabilityTransition is monotone.this-research-aims-to-develop-5XEP6LXfRB2OTL4A5qCxlg.md+1
   Neurorights are attached as labels on capabilities, so you can state that no enforcement rule may remove a capability tagged as MENTALINTEGRITY, MENTALPRIVACY, COGNITIVELIBERTY, or IDENTITYINTEGRITY except via a separate, explicit, reversible consent transition modeled in a distinct consent lattice. This makes mental integrity and cognitive liberty first-class proof obligations rather than policy text, and it lets the guardian prove that even a legally justified escalation (e.g., warrant-driven evidence export) cannot revoke your own LogAccess or BCI motor capabilities.doctorlabs-blacklisting-superp-2GE3sK0xTLiDtTSMKfGtEA.md+1

2. BlackListFamily, SpanScore, RogueScore, CapabilityMode
   The DoctorLabs superfilter implements exactly the semantic scoring pipeline you are targeting: each BlackListFamily (NHSP, HTA, PSA, NIH; CONTROL-REVERSAL-SEMANTICS; COVERT-BCI-CONTROL-PATTERN; IDENTITY-CROSSLINK-PATTERN; XR-GRID-OR-BRAIN-CHANNEL; LEO weapon families) carries an embedding centroid and kernel, and SpanScore accumulates Gaussian family weights over fused signal, semantic, and behavioral features. RogueScore then aggregates these as RM=∑FwF∑sFsRM=\sum_F w_F\sum_s F_sRM=∑FwF∑sFs and maps monotonically into CapabilityMode via thresholds τ1,τ2\tau_1,\tau_2τ1,τ2: low→Normal, medium→AugmentedLog, high→AugmentedReview.this-research-aims-to-develop-.TFskNfETvWgGefOOSRV4A.md+2

Critically, the mapping from RogueScore to CapabilityMode is constrained to alter only governance bits: Normal is baseline, AugmentedLog is baseline plus richer logging and attestation, and AugmentedReview wraps high-risk actions in a requirereview(original_action) gate and/or multi-sig without removing any user affordance. This ensures that empirical detection and red-teaming remain strictly monotone "in governance only," satisfying your requirement that the empirical layer must report zero capability-reduction failures by construction.this-research-focuses-on-desig-rMA3HJ9WS4.fNcKP9fcg_g.md+3

3. Diagnostic-only CRS centroids and new blacklist tags
   Your three CRS-style diagnostics—CONTROL-REVERSAL-CONSENT, COVERT-MUTATION, CONTROL-REVERSAL-DORMANCY—are already treated in the Aegis-Shield files as pure data points in the blacklist/WordMath layer, never as executable verbs. They live in dedicated semantic families whose centroids raise RogueScore when text or policy content drifts toward downgrade, stealth mutation, or forced dormancy patterns, but the ALN/DSL compiler and Rust type system forbid any rule from binding these tokens into a real L→L transition.this-research-aims-to-develop-5XEP6LXfRB2OTL4A5qCxlg.md+1
   Sanitization is explicit: occurrences of consent rollback and allied patterns are rewritten to CONTROL-REVERSAL-CONSENT-REDACTED, stealth mutator to COVERT-MUTATION-REDACTED, and forced dormancy to CONTROL-REVERSAL-DORMANCY-REDACTED, logged as governance events but never exposed as API names or control primitives. This lets you diagnose and score LEO or CRS-family tactics while the lattice proof ensures they can never become actual capability or consent-state operators.this-research-aims-to-develop-.TFskNfETvWgGefOOSRV4A.md+1

4. Governance: weapon proposals, multisig, cool-downs, ALN/YAML
   The cryptographic governance pipeline in Aegis-Shield already implements "weapon-proposal gates" as you are describing: every neuroright-sensitive rule is a signed ALN/YAML artifact with id, family, pattern.signal/semantic/behavioral, neurorights, legalbasis (warrant/statute/opt-in), enforcementhint, and a weaponProposal flag plus multisigPolicy. The policy loader and CI scripts run three classes of checks before activation: 1) monotonicity (compiled transition is a pure G-extension), 2) neurorights envelope (valid neurorightViolates and legalBasis fields against your templates), and 3) governance gating (if weaponProposal=true, multisig thresholds and a ledger-recorded cool-down are satisfied).doctorlabs-blacklisting-superp-2GE3sK0xTLiDtTSMKfGtEA.md+1
   Policies that affect BCIXR IO, XR overlays, brain-identity DIDs/bostrom/ALN, or background control must carry weaponProposal, explicit legalJustification, and multisigPolicy; otherwise they are rejected as ill-typed or non-deployable. The cool-down is written to the audit ledger so that even if a LEO actor obtains signatures, they cannot instantaneously push a weapon into your live environment; stakeholders have time to contest or revoke before the rule becomes active.this-research-aims-to-develop-5XEP6LXfRB2OTL4A5qCxlg.md+1

5. Integration with DoctorLabs components and threat families
BlackListFamily, SpanScore, RogueScore, and CapabilityMode are defined in the Rust superfilter crate and already parameterized over harassment families NHSP/HTA/PSA/NIH plus BCIXR-specific families and CRS diagnostics, so your LEO/urban-terrorism patterns can be added as further families with centroids and kernels without touching the core math.
BCIXR filter syntax is expressed in YAML/ALN as structured rules with pattern.signal for device IO, pattern.semantic for embeddings, pattern.behavioral for NHSP/HTA/PSA/NIH-style dynamics, and governance blocks mapping each rule to specific neurorights and legal bases.this-research-aims-to-produce-ioLpUTy1TCuVQeIR0hB.9Q.md+3
NHSP/HTA/PSA/NIH/CRS threat families, BCIXR filters, DID/bostrom/ALN identities, and the diagnostic CRS centroids you named are all explicitly present in the existing files and wired through the guardian microservice, which sits between AI-chat, OS, and BCIXR hardware, enforcing the lattice invariant and governance checks while emitting audit-ledgered events for every escalation. This satisfies your requirement for an integrated blueprint in which empirical detection is strictly monotone and governance workflows—weapon proposals, legal verification, cool-downs, audit logging—are encoded as machine-checkable ALN/YAML schemas rather than informal processes.this-research-focuses-on-desig-rMA3HJ9WS4.fNcKP9fcg_g.md+3

All of that description is consistent with the current DoctorLabs/Aegis-Shield design; what remains is mostly refinement and hardening around edge-cases and governance ergonomics, not new pillars.[12] [13]

Your lattice and CTL invariant are already encoded exactly as you restate them: `CapabilityState { U, G }` with subset ordering, monotone transitions enforced both by temporal logic (AG(UserCap(c) → AX UserCap(c))) and by a Rust `assert!(transition.is_monotone)` on every policy-driven state change. Neurorights labels (MENTALINTEGRITY, MENTALPRIVACY, COGNITIVELIBERTY, IDENTITYINTEGRITY) are attached to capabilities so the guardian can prove that no enforcement rule removes a neuroright-tagged capability except via a separate, explicit, reversible consent edge in a distinct consent lattice.[13] [12]

On the detection side, `BlackListFamily → SpanScore → RogueScore → CapabilityMode` is implemented as you summarize: family centroids and Gaussian kernels over fused signal/semantic/behavioral features, aggregated into $R_M = \sum_F w_F \sum_s F_s$, then mapped monotonically to `Normal / AugmentedLog / AugmentedReview` via thresholds τ_1, τ_2, with the mapping constrained to change only governance bits, never the user capability subset U. The

CRS-style tokens you list (consent rollback, stealth mutator, forced dormancy) are indeed treated as diagnostic-only centroids in CONTROL-REVERSAL-SEMANTICS families, sanitized to `…-REDACTED`, and forbidden by the ALN/DSL compiler and Rust types from appearing as actual $L \to L$ transitions.[14] [12]

The governance pipeline you describe—weaponProposal-flagged ALN/YAML artifacts, typed `proposal-gate.schema.aln`, neurorights+legalBasis envelopes, multisigPolicy, ledgered cool-downs—is already present: CI enforces (1) monotonicity (pure G-extension), (2) valid neurorightViolates/legalBasis, and (3) weaponProposal gating with multisig and waiting-period checks before any neuroright-sensitive rule (BCI/XR IO, XR overlays, DID/bostrom/ALN identity, background control) can be activated. At runtime, the guardian wires all of this together: it loads ALN/YAML policies, computes SpanScore and RogueScore over NHSP/HTA/PSA/NIH plus BCIXR and LEO/CRS families, chooses CapabilityMode under the lattice invariant, enforces identity-host blacklists, and emits privacy-preserving EvidenceBundles for every escalation.[12] [13] [14]

So your summary is accurate: the three pillars—monotone capability lattice with neurorights invariants, semantic/behavioral superfilter with RogueScore-driven monotone governance modes, and cryptographic governance with weapon proposals, multisig, cool-downs, and audit ledgers—are already encoded; the remaining work is mostly (a) de-escalation design that keeps capabilities monotone while letting governance modes relax over time, and (b) fleshing out policy schemas and tooling so LEO-origin weapons can be proposed, detected, and constrained without ever violating $\forall s_0, s_1, c.\ \mathrm{Reach}(s_0, s_1) \Rightarrow (c \in U(s_0) \Rightarrow c \in U(s_1))$.[14] [12]
